1 Assignment 3

1.1 Problem 1: Design a Correct Partition Algorithm

You are given code below for an incorrect partition algorithm that fails to partition arrays wrongly or cause out of bounds access in arrays. The comments include the invariants the algorithm wishes to maintain and will help you debug.

Your goal is to write test cases that demonstrate that the partitioning will fail in various ways.

```
[1]: def swap(a, i, j):
         assert 0 <= i < len(a), f'accessing index {i} beyond end of array {len(a)}'
         assert 0 <= j < len(a), f'accessing index {j} beyond end of array {len(a)}'
         a[i], a[j] = a[j], a[i]
     def tryPartition(a):
         # implementation of Lomuto partitioning algorithm
         n = len(a)
         pivot = a[n-1] # choose last element as the pivot.
         i,j = 0,0  # initialize i and j both to be 0
         for j in range(n-1): # j = 0 to n-2 (inclusive)
             \# Invariant: a[0] .. a[i] are \Leftarrow pivot
                           a[i+1]...a[j-1] are > pivot
             if a[j] <= pivot:</pre>
                 swap(a, i+1, j)
                 i = i + 1
         swap(a, i+1, n-1) # place pivot in its correct place.
         return i+1 # return the index where we placed the pivot
```

First write a function that will return True if an array is correctly partitioned at index k. I.e, all elements at indices < k are all <= a[k] and all elements indices > k are all > a[k]

```
[49]: def testIfPartitioned(a, k):

# TODO : test if all elements at indices < k are all <= a[k]

# and all elements at indices > k are all > a[k]

# return TRUE if the array is correctly partitioned around a[k] and return

→FALSE otherwise

assert 0 <= k < len(a) # k has to be between index 0 and length of array a
```

```
[50]: assert testIfPartitioned([-1, 5, 2, 3, 4, 8, 9, 14, 10, 23],5) == True, 'Test_U →# 1 failed.'
assert testIfPartitioned([-1, 5, 2, 3, 4, 8, 9, 14, 11, 23],4) == False, 'Test_U →# 2 failed.'
assert testIfPartitioned([-1, 5, 2, 3, 4, 8, 9, 14, 23, 21],0) == True, 'Test_U →# 3 failed.'
assert testIfPartitioned([-1, 5, 2, 3, 4, 8, 9, 14, 22, 23],9) == True, 'Test_U →# 4 failed.'
assert testIfPartitioned([-1, 5, 2, 3, 4, 8, 9, 14, 8, 23],5) == False, 'Test_U →# 5 failed.'
assert testIfPartitioned([-1, 5, 2, 3, 4, 8, 9, 14, 8, 23],5) == False, 'Test_U →# 6 failed.'
assert testIfPartitioned([4, 4, 4, 4, 4, 8, 9, 13, 9, 11],4) == True, 'Test #U →7 failed.'
print('Passed all tests (10 points)')
```

Passed all tests (10 points)

```
[58]: # Write an array called a1 that will be incorrectly partitioned by the
      → tryPartition algorithm above
      # Your input when run on tryPartition algorithm should raise an out of bounds \sqcup
      → array access exception
      # in the swap function or fail to partition correctly.
      a1 = [1, 1, 1, 1, 1, 1]
      ## Define an array a1 below of length > 0 that will be incorrectly partitioned \Box
      →by tryPartition algorithm.
      ## We will test whether your solution works in the subsequent cells.
      # your code here
      assert(len(a1) > 0)

      → tryPartition algorithm above
      # Your input when run on tryPartition algorithm should raise an out of bounds,
      →array access exception
      # in the swap function or fail to partition correctly.
```

```
# a2 must be different from a1
# your code here
a2 = [1, 1, 1, 1, 1, 2]
assert(len(a2) > 0)
assert (a1 != a2)
# Write an array called a3 that will be incorrectly partitioned by the
→ tryPartition algorithm above
# Your input when run on tryPartition algorithm should raise an out of bounds_
→array access exception
# in the swap function or fail to partition correctly.
# a3 must be different from a1, a2
# your code here
a3 = [-1, 0, 1, 99]
assert(len(a3) > 0)
assert (a3 != a2)
assert (a3 != a1)
def dummyFunction():
   pass
```

[]: # your code here

```
[59]: try:
          j1 = tryPartition(a1)
          assert not testIfPartitioned(a1, j1)
          print('Partitioning was unsuccessful - this is what you were asked to break⊔

→the code')
      except Exception as e:
          print(f'Assertion failed \{e\} - this is fine since you were asked to break \sqcup
       →the code.')
      try:
          j2 = tryPartition(a2)
          assert not testIfPartitioned(a2, j2)
      except Exception as e:
          print(f'Assertion failed {e} - this is fine since you were asked to break ∪
       →the code.')
      try:
          j3 = tryPartition(a3)
          assert not testIfPartitioned(a3, j3)
```

```
except Exception as e:
    print(f'Assertion failed {e} - this is fine since you were asked to break
    →the code.')

dummyFunction()

print('Passed 5 points!')
```

Assertion failed accessing index 6 beyond end of array 6 - this is fine since you were asked to break the code.

Assertion failed accessing index 6 beyond end of array 6 - this is fine since you were asked to break the code.

Assertion failed accessing index 4 beyond end of array 4 - this is fine since you were asked to break the code.

Passed 5 points!

1.1.1 Debug the function

Point out where the bug is and what the fix is for the tryPartition function. Note that the answer below is not graded.

This is something that was explicitly pointed out in the lecture. In pseudocode convention, array starts at position 1 and ends at n. In python, arrays start at position 0, so we must shift everything 1 value to the left. For example: i = -1 and j = 0. In the above tryPartition function, both i and j started at 0, so the value of i extended beyond the length of the array and created the exception error.

1.2 Problem 2. Rapid Sorting of Arrays with Bounded Number of Elements.

Thus far, we have presented sorting algorithms that are comparison-based. Ie., they make no assumptions about the elements in the array just that we have a \leq comparison operator. We now ask you to develop a rapid sorting algorithm for an array of size n when it is given to you that all elements in the array are between $1, \ldots, k$ for a given k. Eg., consider an array with n = 100000 elements wherein all elements are between $1, \ldots, k = 100$.

Develop a sorting algorithm using partition that runs in $\Theta(n \times k)$ time for such arrays. **Hint** You can choose your pivots in a simple manner each time.

1.2.1 Part A

Describe your algorithm as pseudocode and argue why it runs in time $\Theta(n \times k)$. This part will not be graded but is intended for your own edification.

1.3 Part B

Complete the implementation of a function boundedSort(a, k) by completing the simplePatition function. Given an array a and a fixed pivot element, it should partition the array "in-place" so that all elements <= pivot are on one side of the array and elements > pivot on the other. You should not create a new array in your code.

```
[60]: def swap(a, i, j):
          assert 0 <= i < len(a), f'accessing index {i} beyond end of array {len(a)}'
          assert 0 <= j < len(a), f'accessing index {j} beyond end of array {len(a)}'</pre>
          a[i], a[j] = a[j], a[i]
      def simplePartition(a, pivot):
          ## To do: partition the array a according to pivot.
          # Your array must be partitioned into two regions - <= pivot followed by \Box
       \rightarrow elements > pivot
          ## If an element at the beginning of the array is already <= pivot in the
       →beginning of the array, it should not
          ## be moved by the algorithm.
          # your code here
          n = len(a)
          \#pivot = a[n-1] \# choose last element as the pivot.
          i,j = -1,0 # initialize i and j
          for j in range(n): # j = 0 to n-1 (inclusive)
              \# Invariant: a[0] .. a[i] are \Leftarrow pivot
                            a[i+1]...a[j] are > pivot
              if a[j] <= pivot:</pre>
                  swap(a, i+1, j)
                  i = i + 1
          swap(a, i+1, n-1) # place pivot in its correct place.
          return i+1
      def boundedSort(a, k):
          for j in range(1, k):
              simplePartition(a, j)
```

```
[61]: a = [1, 3, 6, 1, 5, 4, 1, 1, 2, 3, 3, 1, 3, 5, 2, 2, 4]
    print(a)
    simplePartition(a, 1)
    print(a)
    assert(a[:5] == [1,1,1,1,1]), 'Simple partition test 1 failed'

    simplePartition(a, 2)
    print(a)
    assert(a[:5] == [1,1,1,1,1]), 'Simple partition test 2(A) failed'
    assert(a[:5] == [2,2,2]), 'Simple Partition test 2(B) failed'
```

```
simplePartition(a, 3)
print(a)
assert(a[:5] == [1,1,1,1,1]), 'Simple partition test 3(A) failed'
assert(a[5:8] == [2,2,2]), 'Simple Partition test 3(B) failed'

assert(a[8:12] == [3,3,3,3]), 'Simple Partition test 4(C) failed'
assert(a[12:14] == [4,4]), 'Simple Partition test 4(D) failed'

simplePartition(a, 5)
print(a)
assert(a == [1]*5+[2]*3+[3]*4+[4]*2+[5]*2+[6]), 'Simple Partition test 5 failed'
print('Passed all tests : 10 points!')
```

```
[1, 3, 6, 1, 5, 4, 1, 1, 2, 3, 3, 1, 3, 5, 2, 2, 4]
[1, 1, 1, 1, 1, 4, 6, 3, 2, 3, 3, 5, 3, 5, 2, 2, 4]
[1, 1, 1, 1, 1, 2, 2, 2, 4, 3, 3, 5, 3, 5, 6, 3, 4]
[1, 1, 1, 1, 1, 2, 2, 2, 3, 3, 3, 3, 4, 5, 6, 5, 4]
[1, 1, 1, 1, 1, 2, 2, 2, 3, 3, 3, 3, 4, 4, 5, 5, 6]
[1, 1, 1, 1, 1, 2, 2, 2, 3, 3, 3, 3, 4, 4, 5, 5, 6]
Passed all tests: 10 points!
```

1.4 Problem 3: Design a Universal Family Hash Function

Suppose we are interested in hashing n bit keys into m bit hash values to hash into a table of size

$$2^m$$
. We view our key as a bit vector of n bits in binary. Eg., for $n=4$, the key $14=\begin{pmatrix}1\\1\\1\\0\end{pmatrix}$.

The hash family is defined by random boolean matrices H with m rows and n columns. To compute the hash function, we perform a matrix multiplication. Eg., with m=3 and n=4, we can have a matrix H such as

$$H = \left[\begin{array}{cccc} 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 \end{array} \right]$$

The value of the hash function H(14) is now obtained by multiplying

$$\left[\begin{array}{cccc} 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 \end{array}\right] \times \left(\begin{array}{c} 1 \\ 1 \\ 1 \\ 0 \end{array}\right)$$

The matrix multiplication is carried out using AND for multiplication and XOR instead of addition. For the example above, we compute the value of hash function as

$$\begin{pmatrix} 0 \cdot 1 + 1 \cdot 1 + 0 \cdot 1 + 1 \cdot 0 \\ 1 \cdot 1 + 0 \cdot 1 + 0 \cdot 1 + 0 \cdot 0 \\ 1 \cdot 1 + 0 \cdot 1 + 1 \cdot 1 + 1 \cdot 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \\ 0 \end{pmatrix}$$

(A) For a given matrix H and two keys x, y that differ only in their i^{th} bits, provide a condition for Hx = Hy holding. (**Hint** It may help to play with examples where you have two numbers x, y that just differ at a particular bit position. Figure out which entries in the matrix are multiplied with these bits that differ).

If x and y differ in their ith bits, let's assume that xi = 1 and yi = 0. In order for Hx = Hy to hold, H must be 0.

(B) Prove that the probability that two keys x, y such that $x \neq y$ collide under the random choice of a matrix x, y is at most $\frac{1}{2^m}$.

YOUR ANSWER HERE

```
[175]: import random
       def dot_product(lst_a, lst_b):
           and_list = [elt_a * elt_b for (elt_a, elt_b) in zip(lst_a, lst_b)]
           return 0 if sum(and_list)% 2 == 0 else 1 #return 0 if the remainder of_
        \rightarrow sum(and list) / 2 is 0, else return 1.
           #return and list
       # encode a matrix as a list of lists with each row as a list.
       # for instance, the example above is written as the matrix
       # H = [[0,1,0,1],[1,0,0,0],[1,0,1,1]]
       # encode column vectors simply as a list of elements.
       # you can use the dot_product function provided to you.
       def matrix multiplication(H, lst):
           result = []
           \#i = 0
           for i in range(len(H)):
               result += [dot_product(H[i], lst)]

      Tests passed: 10 points!
```

1.5 Manually Graded Answers

1.5.1 Problem 1

The bug is in the initialization of i in the algorithm. It must be i = -1 rather than i = 0. Due to this, either the first element of the array is never considered during the partition or there could be an access to i+1 that is out of array bounds.

1.5.2 Problem 2 A

```
for k = 1 to n
j = partition array a with k as pivot
```

The running time is $\Theta(n \times k)$.

1.5.3 Problem 3 A

Since x, y differe only in their i^{th} bits, we can assume $x_i = 0$ and $y_i = 1$. Therefore, $Hx + H_i = Hy$ wherein, + refers to entrywise XOR and H_i is the i^{th} column of H. Thus, Hx = Hy if and only if H_i has all zeros. This happens with probability $\frac{1}{2^m}$.

1.5.4 Problem 3 B

Let us assume that x and y differ in k out of n positions. We know that Hx = Hy if and only if Hx + Hy = 0 where + is XOR and 0 is the vector of all zeros. But Hx + Hy = H(x + y) since AND distributes over XOR.

Whenever x and y agree in the i^{th} entries, we have the i^{th} entry of (x + y) is zero. Therefore, H(x + y) is just the XOR sum of k columns of H corresponding to positions where x and y differ.

Thus, one of the columns must equal the sum of the remaining k-1 columns. Let us fix these k-1 columns as given and the last column as randomly chosen. The probability that each of the m entries of the last column matches the sum of the first k-1 column is $\frac{1}{2^m}$.

1.6 That's all folks
